We present a comprehensive experimental study on the influence of laser cutting on the flexural strength of 0.63 mm thick alumina sheets. In this study ceramic specimens are cut to a size of 24×3 mm² with the flexural strength being measured using a 3 point bending test. Based on a design of experiments approach the results reveal that among the experimental parameters the laser focus position has the highest influence on the flexural strength, reducing it by 63 MPa. Cutting alumina at 300 mm/s yields a flexural strength of 395 MPa, which is significantly lower as compared with reference samples produced by scribe and break having a flexural strength of 520 MPa. Yet, a comparable flexural strength of 311 MPa using a CO₂ laser is achieved at only 20 mm/s. To cut small contours, digital modulation of the fiber laser output power is employed leading to a flexural strength of 506 MPa at 1 mm/s and 469 MPa at 10 mm/s. Further results show that additional outer contours can halve the flexural strength and the lack of rounding reduces the flexural strength further. Inner contours especially with corners are also decreasing the flexural strength drastically while an inner circle causes only low strength reduction.

Keywords: Laser cutting, alumina, crack formation, fiber laser, flexural strength

1. Introduction

In the last decade there is an increasing demand in ceramic substrates made of alumina for the electronic industry. Electronics on ceramic substrates are found in, e.g., automotive, telecommunication, power electronics and various sensor systems. Ceramic substrates have many advantages over paper and glass fiber reinforced plastics with one of the most important ones being their high thermal conductivity. Standard and frequently used FR4 has a thermal conductivity of 0.3 W/mK, while alumina is characterized by 25 W/mK. As a result, the need of additional cooling is reduced when using ceramic substrates [1]. Further advantages of alumina compared to standard FR4 substrates are the chemical inertness and the much higher maximum operation temperature [2].

Due to its high Vickers hardness of 1600 HV1 and brittleness the only mechanical method processing alumina is diamond abrasive cutting [3]. But even diamond grinding tends to result in low processing speeds and high tool wear as well as the danger of mechanical breakup. Therefore, different laser processing strategies are commonly in use. In order to reach high velocities during separating straight lines, mostly CO₂ lasers are industrially employed for the scribe and break method [4]. This process has the advantage of a low required laser power and it is possible to run additional manufacturing steps between scribing and breaking.

For more complex contours usually laser fusion cutting is used. Using this technique Black and Chua [5] cut complex contours even in 9.2 mm thick alumina with a power modulated 530 W CO₂ laser at 1.5 mm/s but having major problems with cracks. Hong et al. [6] separated silicon ni-

tride ceramics with a 250 W Q-switched CO₂ Laser in a multi-pass process at an effective cutting velocity of 1 mm/s. In this process a higher velocity of the single passes of about 220 mm/s leads to less crack formations. Ji et al. [7] cut 10 mm thick alumina using a pulsed CO₂ laser with 3.5 kW peak power at 0.3 mm/s without breakup of the substrate. Other research topics in laser cutting of ceramics is described by Wee et al. [8] who found that by cutting 7 mm thick alumina with a 1.2 kW CO₂ Laser the striation angle and the striation wavelength are mainly influenced by the laser material interaction time and the gas pressure.

To predict cracks induced by the thermal stress during laser cutting Lee and Ahn [9] developed a Bayesian Probabilistic Model suggesting that cracks mainly depend on the cutting front angle. Another approach to predict cracks was presented by Yilbas et al. [10] using thermal simulations showing that cracks are mainly caused by the resolidification of molten material in the cut kerf. Yan et al. [11] performed experiments cutting 6 mm thick alumina with a 3.5 kW CO₂ Laser at different pulse mode showing that fewer pulses with more energy but large switch off times create less stress than many pulses with lower pulse energy.

To avoid cracks in micro processing ceramics Wang et al. [12] presented results on cutting holes in 0.63 mm thick alumina substrates using a 150 femtosecond short pulse laser with an average power of 0.8 W in a multi pass process. The authors achieved very high cutting quality but only an effective velocity of 1.5 μm/s, which is much too slow for industrial applications. The use of excimer laser (248 nm KrF) by Lump and Allen [13] in cutting vias into

0.63 mm thick alumina nitride showing good quality but also revealing major problems with cracks. With 3 000 pulses for one via at 50 Hertz laser repetition rate the process is also too slow for industrial applications.

The literature reveals that for cutting complex contours or vias in alumina only fusion cutting offers a fast process with high quality. The disadvantage of fusion cutting is, however, the generation of thermal induced stress and cracks leading to the reduction in strength of the material [10]. In this contribution, we examine the influence of laser fusion cutting with a single mode fiber laser on the flexural strength of alumina and maximize the flexural strength by parameter optimization. The results are compared with the flexural strength after separation with scribe and break and with CO₂ laser cuts. Further we measure the strength change by cutting inner and outer contours.

2. Experimental

2.1 Laser system

In this study, a continuous wave 500 W single mode fiber laser (IPG Photonics) is used for fusion cutting. The laser system is equipped with linear stages (x,y) for the workpiece (Aerotech) and a fine cutting head (Precitec) attached to a linear drive (z). The assisted gas nitrogen with purity greater than 99.999 % flows coaxial to the laser beam. The gas nozzle has a diameter of 0.3 mm and the gas pressure can be adjusted between 4 and 20 bar. The distance between the nozzle and the workpiece is positioned by the z-linear drive to 0.3 mm. The specified laser emission wavelength is 1070 nm in conjunction with a beam propagation factor of M² < 1.1. The raw beam diameter of 7.25 mm is focused by a lens with focal length of 50 mm. The resulting Rayleigh length and the focus diameter are calculated to 70 μm and 11 μm, respectively. The Laser system is equipped with a position synchronous output (PSO) to modulate the laser digitally. The maximum digital modulation frequency for the laser is 50 kHz. Using the PSO, the laser is switched on for an adjustable time after the drives moved a given distance. With the PSO the energy input per unit length is kept constant during acceleration and deceleration paths (i.e. during cutting a corner).

To compare cutting results with traditional CO₂ lasers, a 200 W CO₂ laser system (Synrad) is used. The system consists of 3-D linear stages (Aerotech) with a maximum velocity of 500 mm/s. The assist gas nitrogen flows through a coaxial nozzle with 0.5 mm diameter to the workpiece. The laser emits a beam with 11.7 mm diameter and a M² of 1.2. The beam is focus in a Precitec cutting head with a 50 mm focal length. The focus diameter is calculated to 70 μm with a Rayleigh length of 300 μm.

2.2 Ceramic Material

For our study, commercially available alumina sheets (CeramTec) having a thickness of 0.63 mm are used, a thickness which is most common in the electronic industry. The material is specified by a compositional purity of larger than 98%, a density of 3.8 g/cm³, a Vickers hardness HV1 of 1600 and a linear thermal expansion coefficient of 7.2×10⁻⁶ K⁻¹, respectively. The flexural strength is specified

to 390 MPa in conjunction with a Weibull modulus of 10. In order to run bending tests, these ceramic sheets are laser cut into 24 mm long and 3 mm wide samples. For this cutting process also the optical properties are of importance. At the wavelength of the employed fiber laser (1070 nm) alumina has a high reflectance of 79% at room temperature [14]. More important, however, than the reflectance at room temperature (contributing only to the cut-in phase) is the absorption of hot and molten alumina during laser cutting. For this reason Zhang and Modest [15] published experimental results showing that alumina has an absorption higher than 90 % around 1064nm at temperatures higher than the melting point. Please note that in contrast to 1064 nm the absorption around 10600 nm (i.e. the of the CO₂ radiation wavelength) in alumina is about 95 % [16].

2.3 Flexural strength measurement

To measure the flexural strength, a 3-point bending test machine (Thuemler) is used with 20 mm distance between the two contact points. The flexural strength σ is calculated with formula (1) from the maximum force F which the sample withstands before braking. Here l is the distance between the two contact points, b stands for the width of the sample and d expresses the sample thickness. The velocity of the bending test is set to 1 mm/min like recommended by Bengisu [2].

$$\sigma = \frac{3 \cdot F \cdot l}{2 \cdot b \cdot d^2} \quad (1)$$

In contrast to metals, where the strength is Gaussian distributed, for ceramics it is Weibull distributed. In ceramics a failure in one region can't get compensated due to the lack of ductility. As a consequence the strength of ceramics is described as the minimum strength of all filaments in the material due to the lack of ductility [17]. This extreme value behavior is described well with the Weibull distribution.

Opposite to the 4 point bending test, in which a constant stress between the two inner points is provided, the stress in the 3 point bending test geometry is concentrated in a small area around the middle point [2]. This results to a smaller stressed volume in the 3 point test geometry and as a consequence to a lower probability of having a weak filament within this area. Therefore, the flexural strength in a 3 point bending test is typically higher as compared to a 4 point bending test.

3. Results

3.1 Reference cut with scribe and break

For comparison reasons sample geometries (24×3 mm²) of alumina were produced by the scribe and break method. Using a 20 W pulsed fiber laser at 1 mJ pulse energy and 20 kHz pulse frequency the sample is scribed in a multi pass process about 130 microns deep. Afterwards the scribed ceramic is broken mechanically. Figure 1 shows the braked edge after scribing where no cracks can be seen on the braking edge. The flexural strength of this samples is

measured to 520 MPa which is significantly higher than the specified value of 390 MPa, given by the supplier.

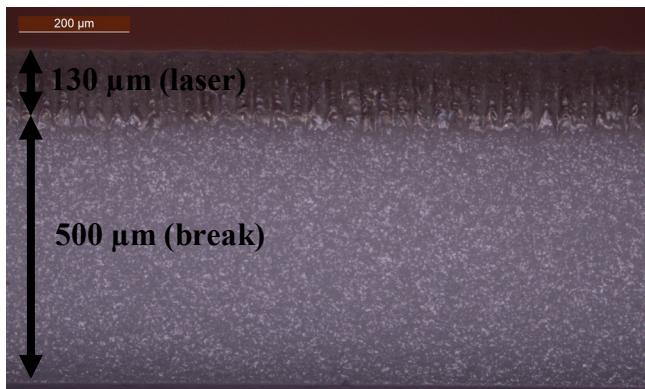

Figure 1: Braked edge after scribing with pulse laser.

3.2 Fusion cutting using CO₂ laser

In this section, the influence of fusion cutting with a continuous wave CO₂ laser on the flexural strength of the ceramic is evaluated. The CO₂ laser operates at 200 W and the distance between nozzle and workpiece is set to 0.5 mm. The focus position is placed onto the surface of the ceramic. At a velocity of 20 mm/s and 8 bar gas pressure a cut without mechanical breakup is achieved. Figure 2 shows the cutting edge processed with the CO₂ laser at 20 mm/s. The thickness of the glassy phase at the cut kerf is measured between 10 μm and 40 μm. The flexural strength of the samples strongly depends on the cutting velocity. At 5 mm/s a flexural strength of 188 MPa is measured, at 10 mm/s the flexural strength increases to 281 MPa and reach a maximum of 311 MPa at 20 mm/s. It is assumed that at higher velocities the laser dwell time at one point is lower which results in less heat diffusion into the material. As a result, the crack depth is reduced and as a consequence the mechanical strength increases. When cutting with CO₂ laser at 20 mm/s the strength of alumina decreases by 40 % as compared to scribe and break. The energy input per unit length is 10 J/mm which is halve of the track energy that Yilbas et al. [10] used for cutting 1.5 mm thick alumina (2 kW CO₂ laser at 100 mm/s). In contrast, Huehnlein et al. [18] required only 1.5 J/mm for cutting 0.25 mm alumina with a CO₂ laser (180 W at 120 mm/s).

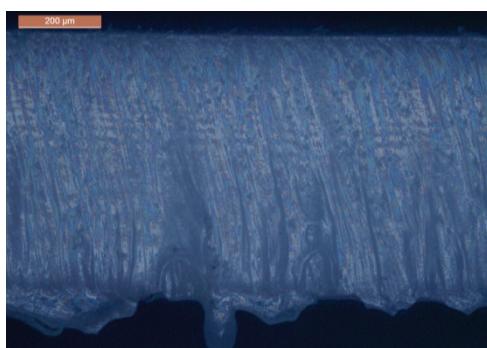

Figure 2: Cutting edge cut with CO₂ laser at 20 mm/s

3.3 Fusion cutting using continuous wave fiber laser

To evaluate the influence of different machine parameters a linear experimental design, described by Siebertz et al. [19], with 4 parameters (shown in Table 1) and 16 experiments is run. A similar design setup is often used for optimizing laser processes, e.g. by Dhupal et al. [20] to optimize micro grooving of aluminum titanate or by Yang et al. [21] to analyze cutting of PMMA. To achieve high productivity the laser power is fixed to the maximum of 500 W. The flexural strength is measured for every parameter combination and the influences of the laser parameters, shown in Table 1, are calculated with commercial statistics software (JMP®). In this analysis, those parameter combinations resulting in a breakup during cutting are evaluated with 0 MPa. Table 1 shows that the position of the focus has the most important influence on the flexural strength. The negative value of this influence expresses a higher strength at lower focus positions (a negative focus position indicates a focus position below the surface of the workpiece). In contrast, the velocity has no significant influence within the analyzed interval. The negative influences of the nozzle diameter and gas pressure reveal that too much gas leads to lower strength. Possible reasons are the mechanical force of the gas on the cut kerf and the

Table 1: Influence of laser parameters on the flexural strength. A negative influence expresses a strength reduction with increasing parameter value

Parameter	Parameter Space	Influence on strength
Position of focus	-0.5 mm to -0.1 mm	-63 MPa
	0.3 mm to 0.8 mm	-29 MPa
Nozzle diameter	6 bar to 12 bar	-23 MPa
	50 mm/s to 300 mm/s	-0.5 MPa
Velocity		

amount of re-solidifying melt.

Figure 3 shows the influence of the focus position and the gas pressure on the flexural strength graphically in a surface plot. It can be seen that the highest strength is achieved at low gas pressure and a low focus position. Further it is shown that the strength decreases with increasing focus position and gas pressure, which is expressed in Table 1 by the negative influences. At different parameter combinations, the crack network looks very different with respect to the distance between cracks, their orientation, curvature and visibility of the cracks because they are covered with re-solidified melt. In our study, a correlation between the shape of the crack network and flexural strength wasn't found. A possible reason for that is given by Modest [22] who simulated thermal stress during CO₂ laser drilling of SiC. He found that the cracks seen at the surface only pervades a very thin layer near the process zone. In contrast,

he assumes that the high temperature gradients which cause tensile stress are responsible for cracks below the surface result in mechanical breakup.

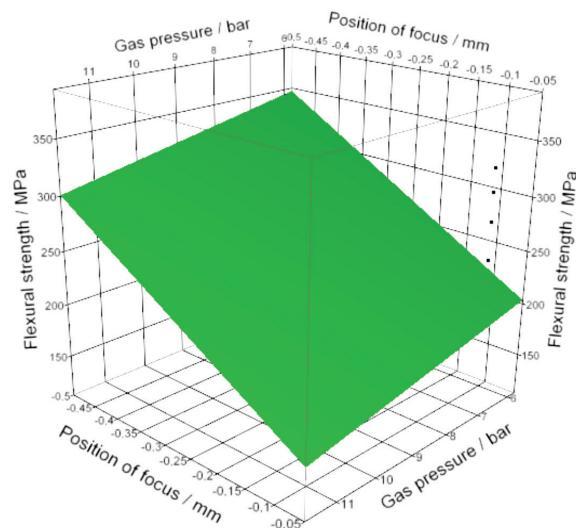

Figure 3: Contour plot of the flexural strength as a function of focus position and gas pressure in cw fiber laser cutting

The maximum flexural strength measured in these experiments of 395 MPa is achieved with the parameter combination velocity 300 mm/s, gas pressure 6 bar, position of focus 0.5 mm below workpiece surface and nozzle diameter 0.8 mm. Please note, that the position of the focus (calculated to 11 µm diameter) is only 0.13 mm above the bottom of the substrate. Due to the short focal length of the lens the beam expands to 72 µm at the surface. The flexural strength value of 395 MPa is as high as the specification of 390 MPa, yet lower than the value determined by scribe and break. This parameter combination results in an energy input per unit length of 1.7 J/mm at 300 mm/s and 500 W. This is less than 2.5 J/mm Huehnlein et al. [18] applied for cutting 0.25 mm alumina with a single mode fiber laser (250 W at 100 mm/s). Compared to CO₂ laser cutting in section 3.2 where a track energy of 10 J/mm is required the energy input per unit length for fiber laser cutting is much lower due to the smaller focus diameter.

Figure 4 shows the cutting edge of alumina with a parameter combination similar to that leading to the highest flexural strength, however with a lower cutting velocity of

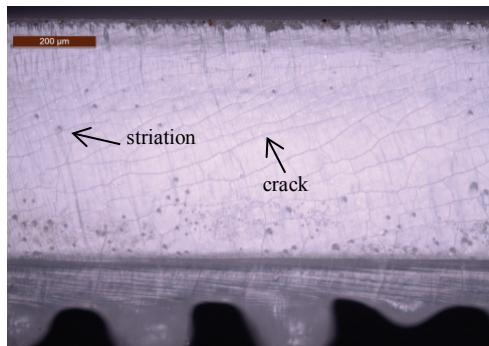

Figure 4: Cutting edge produced by cw fiber laser cutting

100 mm/s and a smaller nozzle diameter. In this regime the crack network can be clearly seen. The re-solidified melt forms a glassy phase with a thickness of a few microns. The thickness is measured with depth of sharpness method by focusing with the microscope on the striations and then focusing on the crack network in the ceramic. The distance between these two focus levels is the thickness of the glassy phase. The striations in the glassy phase are always perpendicular to the cracks. In Figure 4 the striations are parallel with an angle of 15° to the vertical. At higher velocities of 300 mm/s the striations get swirled and therefore the crack network changes its shape. Here it should be considered that alumina has a 2 to 3 orders of magnitude higher viscosity at melt temperature than steel [23]. Based on thermal simulations, Yilbas *et. al.* [10] found that cracks are caused by the re-solidification of the glassy phase. The re-solidification generates different forces parallel and perpendicular to the striations. This complements with the cracks in Figure 4 being perpendicular to the striations.

To measure the width of the cracks a scanning electron microscope (SEM) with an acceleration voltage of 10 kV is used. The cracks in Figure 5 are measured to a width between 0.1 microns and 1 micron. This is still below the mean grain size given by the manufacturer between 2 microns to 5 microns. Usually the depth of the cracks is much higher than the width. As a result the cracks can be deeper than the grain size which leads to significant influences on the strength.

According to the Griffith equation [24] the stress for a brittle fracture σ_c of materials with cracks can be calculated with formula (2) from the elastic modulus E and the specific surface energy γ .

$$\sigma_c = \sqrt{\frac{2\gamma E}{\pi c}} \quad (2)$$

With increasing crack depth c the stress for a brittle fracture caused by cracks decreases. When this stress falls below the specified flexural strength of the material, the measured strength also decreases. It is assumed that the cracks in cw fiber laser cutting are deep enough to influence the flexural strength. In CO₂ laser cutting, the flexural strength is lower compared to fiber laser cutting, which can be explained by deeper cracks which are obscured by re-solidified melt.

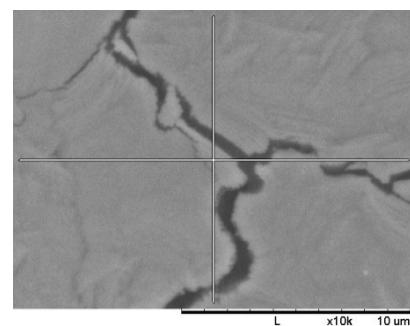

Figure 5: SEM image of cracks caused by cw cutting

3.4 Fusion cutting using modulated fiber laser

In order to cut small contours, the linear drives of the laser system have to decelerate before and accelerate behind corners. Therefore, the velocity of 300 mm/s cannot be held. As a consequence, the energy input per unit length sharply rises at corners. This high energy input in combination with the disadvantage that corners generally weaken the strength of ceramics results in a mechanical breakup of the substrate. To avoid this, the laser is digitally modulated to keep the energy input per unit length constant. Using a velocity of 1 mm/s and a switch on time of 1 ms after the drives travel 10 µm even small and complex contours are cut without breakup (other parameters: position of focus - 0.5 mm, gas pressure 6 bar, nozzle diameter 0.3 mm, laser power 500 W). The travel distance is chosen with respect to the focus diameter of 11 µm. The energy input per unit length is calculated from the pulse energy of 0.5 J (500 W for 1 ms) which occurs after a travel distance of 10 µm (100 pulses per mm) to 50 J/mm. This is much higher than 1.7 J/mm when cutting straight lines in continuous wave mode. The reason for this high energy input per unit length is the cooling of the process zone between two pulses and the therefore lower absorption for the following pulse. A further reason is the thermal conduction that takes more energy away from the process zone at slower velocities.

Figure 6 shows the cutting edge of a digitally modulated cut where the striations at the upper third have a width of about 10 µm that equates the distance between two laser pulses. Due to the surface roughness the re-solidified melt is haze, so possible existing cracks cannot be seen. For instance, a flexural strength of 506 MPa is achieved for cuts using digital modulation which is almost as high as the value for scribe and break. This high strength achieved at low pulse frequency of 100 Hz and 10 % duty cycle corresponds with the results of Yan et al. [11]. The Weibull modulus for this parameter combination is calculated to 29. As a result of the relatively low gas pressure and the narrow cut kerf of about 40 µm, the kerf is closed partially at the lower edge by the dross. To separate the sample from the substrate the samples can be pushed out easily by hand.

In terms of higher productivity it is not recommended to further increase the velocity in this parameter combination even at constant track energy. At higher velocities of

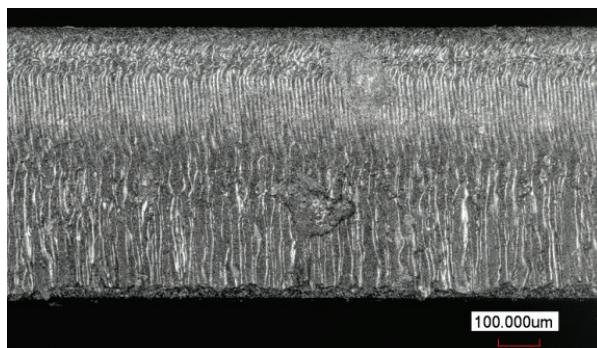

Figure 6: Laser scanning image of cutting edge by digitally modulated cutting at 1 mm/s

3 mm/s the flexural strength is reduced by about 20 % to 398 MPa keeping the other parameters constant. To keep the strength high even at higher velocities requires to either reduce the pulse duration or to increase the distance between the pulses. A reduction of the pulse duration results in an incomplete cut because the power density is too low to melt the ceramic. On the other hand increasing the travel distance between two pulses to 40 µm and therefore reduce the track energy to 12 J/mm a cutting velocity of 10 mm/s is possible. With this parameter combination and a gas pressure of 14 bar a flexural strength of 469 MPa is achieved and the samples are separated completely from the substrate. The benefit of a ten times higher productivity results in a flexural strength reduction of 8 % compared to the cut at 1 mm/s and a decrease of 10 % compared to scribe and break. The cutting edge achieved with this parameter combination is shown in Figure 7. The striations width of 40 µm is as wide as the travel distance between two pulses. The surface roughness is measured to 3.1 µm and therefore similar to the cut at 1 mm/s.

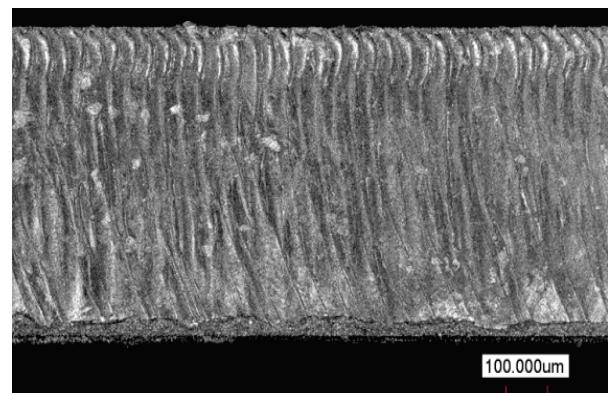

Figure 7: Laser scanning image of cutting edge by digitally modulated cutting at 10 mm/s

To show the ability of cutting complex contours a test design with sharp edges and inner circles is cut. With both parameter combinations the test pattern was cut successfully with high quality. Figure 8 shows a part of this test pattern cut with digital modulation using a velocity of 10 mm/s and 40 µm pulse distance.

Figure 8: Complex contour cut with 10 mm/s with holes between 0.3 mm and 1.1 mm and sharp angles of 30° and 50°

3.5 Influence of the outer contours

In some applications it is necessary to fit the geometry of the substrate to the available space. Therefore in these cases, the substrates need complex outer contours. The designed geometry for this study is shown in Figure 10. On the left hand side the geometry has a width of 3 mm. This is as wide as in the previous experiments. On the right hand side the pattern is one mm wider than on the left. The diminution in the middle is designed with different radii. In the bending machine the pattern is placed with the diminution directly at the middle bending point.

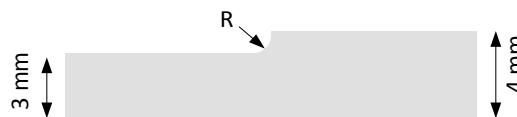

Figure 9: Test pattern for outer contours with variable rounding

The parameters used in this cut are described in section 3.4 with a velocity of 1 mm/s, distance between two pulses of 10 µm and 1 ms pulse duration (other parameters: position of focus -0.5 mm, gas pressure 6 bar, nozzle diameter 0.3 mm, pulse peak laser power 500 W). For the calculation of the flexural strength the smaller width (3 mm) is used. Figure 11 shows the flexural strength as a function of the radius R compared to the reference cut with the same parameter combination from section 3.4. It is obvious that the test pattern, even with a large radius, has a much lower flexural strength than the reference cut. A reason for this is the concentration of the force from the wider part of the sample on the diminution and the general weakness of ceramics at corners. A further effect in corners is the higher thermal load which leads to higher thermal induced stress. Figure 11 also reveals a high reduction of the strength at radii smaller than 0.1 mm. This corresponds with the results of Glaw et al. [25] showing the corner rounding can increase the resistance of a breakup during temperature changes.

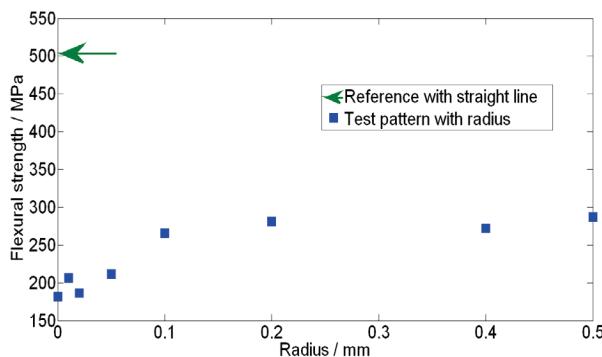

Figure 10: Flexural strength as a function of the rounding radius

3.6 Influence of inner contours

In hybrid circuits it is also necessary to cut holes for vias or mounting purposes. This section is about the influences of different inner contours on the flexural strength of ceramic material. Four test patterns are designed as shown in Figure 9. The width of all samples is 4 mm and the inner contours reduce the width in the middle by 1 mm. However, for the calculation of the flexural strength the effective width of 3 mm is used. The parameter combination used for the experiments is the same than in section 3.5 for the outer contours.

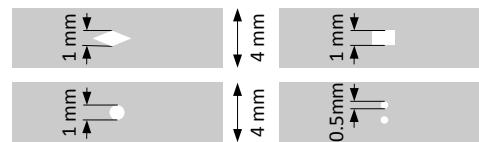

Figure 11: Test pattern for different inner contours

Figure 12 shows the flexural strength of the test pattern compared with the reference cut from section 3.4 using the same parameter combination. The lowest strength is measured cutting a rhombus into the ceramic. In this design the force of the bending machine is focused to the peaks of the rhombus. Due to the lack of ductility the material cannot compensate the stress and results in a breakup. The flexural strength of the sample with the rectangle is 16 % higher than that with the rhombus. The samples break at the corners of the inner rectangle rather than in middle of the rectangle where in a homogeneous material the highest stress results. This corresponds to the results shown in section 3.5, where also the weakness of corners is revealed. Cutting a circle results in the highest flexural strength measured due to the lack of inner corners but the strength is still lower than the reference of the 3 mm wide rectangle. These results show the weakening of alumina structures by inner contours especially inner contours with corners.

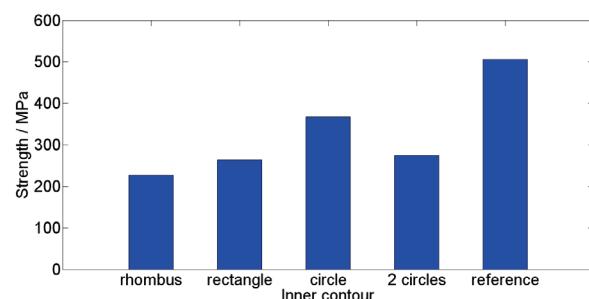

Figure 12: Flexural strength by cutting different inner contours

4. Conclusion

In this contribution the influence of cutting 0.63 mm thick alumina with single mode fiber laser and CO₂ on the flexural strength of the material is analyzed. For these experiments samples with a length of 24 mm and a width of 3 mm are cut and the flexural strength is measured with a 3 point bending test. The results using design of experiments show that the position of the focus has a large and the gas

pressure and nozzle diameter a medium influence on the strength. To cut smaller contours a digital modulation is used to avoid a mechanical breakup of the ceramic. An overview of the flexural strength with different cutting methods is shown in Table 2.

Further results show that additional outer contours can halve the strength and the lack of rounding further amplifies this effect. Inner contours especially with corner are also decreasing the strength drastically while an inner circle causes the lowest strength reduction.

Table 2: Overview about the strength at different cut methods

Modus	Velocity	Strength
Reference by scribe and break		520 MPa
Continuous wave CO ₂	20 mm/s	311 MPa
Continuous wave fiber laser	300 mm/s	395 MPa
Modulated fiber laser 10 μm pulse distance	1 mm/s	506 MPa
Modulated fiber laser 40 μm pulse distance	10 mm/s	469 MPa
