A shorter laser pulse provides smaller heat affected zones and higher ablation accuracy, which are demanded for metal micro-fabrication processes. In particular, picosecond laser systems, which are suitable for operation in industrial environments, are of great interest for many practical applications. However, low productivity has been a limitation to broadening their industrial application. It was recently reported that when micromachining copper with a 1064 nm picosecond laser, a desirable pulse energy and repetition rate exist for achieving the maximum volume ablation rate. In this paper, we used a 515 nm picosecond laser, which is more efficient for micromachining copper in terms of laser energy absorption, and determined its optimum pulse energy and repetition rate. A theoretical analysis based on the experimental data on copper ablation showed that using a 515 nm picosecond laser instead of a 1064 nm picosecond laser is favorable in that the calculated threshold fluence is 75 % lower and the optical penetration depth is 50 % greater.

Keywords: picosecond laser, volume ablation rate, copper, threshold fluence, penetration depth

1. Introduction

Recent advances in the development of ultra-short pulse lasers are making such devices ever more accessible to industries. In particular, ultra-short pulse high-power lasers can now implement non-thermal processing and precision machining at the same time. On this basis, this process has begun to be effectively and broadly applied industrially [1, 2]. At this point, many studies still use an infrared-based ultra-short pulsed laser for patterning [3-6] although a shorter wavelength laser beam can produce much higher average power than before.

In this paper, the 515 nm wavelength of an ultra-short pulse laser was employed to verify its ablation efficiency for patterning copper based on an infrared based theoretical study [3-5, 7]. The purpose of this study is to determine the optimized process parameters, such as fluence and repetition rate, for achieving optimized process efficiency for the ablation of copper using this 515 nm wavelength ultra-short pulse laser beam process.

The results of this study suggest an optimum solution for the micro-machining processes of various metals including copper using a 515 nm wavelength ultra-short pulsed laser.

2. Experimental Setup

Copper is the main material used for printing rolls, and previous studies have shown that the reflectance of copper is reduced by more than half when it is irradiated in the green wavelength (515 nm) as compared with the near-infrared wavelength [3-5, 7, 8]. This means that when a laser beam in the green wavelength is used, the absorption rate is increased by two-fold or more, which leads to further improvement of the ablation efficiency.

3. Theoretical background

The volume ablation rate (dV/dt) was determined as delineated in Eq. (1) [9, 10], which is composed of the average power ($P_{av}$), pulse repetition rate (Rep.), threshold fluence ($F_{th}$), and laser interaction time ($t_i$). The theoretical analysis is performed assuming that the laser pulse is absorbed in the entire region of the beam area, and the generated plasma is instantaneously removed from the ablation region.

$$dV/dt = \frac{\pi r_d^2}{4} \cdot P_{av} \cdot \left(1 - \frac{F_{th}}{F(p)}\right)$$

where $r_d$ is the laser beam radius, $F(p)$ is the fluence at the focal point, and $F_{th}$ is the threshold fluence.
ence ($F_{th}$) and penetration depth ($\delta$). Additionally, the threshold fluence ($F_{th}$) and the absorption coefficient ($1/\alpha$) were determined by Eq. (2) and Eq. (3) [5, 11-13]; these equations can be applied according to sequence as shown in Fig. 2.

$$\frac{dV}{dt} = \frac{1}{4} \cdot \pi \cdot w_0^2 \cdot \delta \cdot \text{Rep} \cdot \ln \left( \frac{2 \cdot P_{\text{av}}}{\text{Rep} \cdot \pi \cdot w_0^2 \cdot F_{th}} \right)$$  \hspace{1cm} (1)

$$F_{th} = F \exp(-r_d^2 / 2w_0^2)$$  \hspace{1cm} (2)

$$L = \frac{1}{\alpha} \ln \left( \frac{F}{F_{th}} \right) = \delta \ln \left( \frac{F}{F_{th}} \right)$$  \hspace{1cm} (3)

According to Eq. (2), to find the threshold fluence ($F_{th}$), the radius of the optical focal point ($w_0$) and the radius of the crater ($r_d$) are required during processing. The applied optical spot size on the focal point was $14.56 \ \mu m$. The diameter of the crater was measured using a non-contact three-dimensional fine shape measuring device and an optical microscope.

4. Results and Discussion

4.1 Dependency of the crater diameter and the threshold fluence

Figure 3 shows the copper surface after the laser beam irradiation, which was performed under a fluence of $0.28 \ J/cm^2$ and 200 pulses. Figure 4 shows the change in the central diameters of the craters produced in copper based on the increase of the total input energy, which is defined by multiplying the fluence and the number of pulses. Depending on the total input energy, the diameter of the crater is shown to finally converge after increasing in the initial stage. The value of each converging diameter increases depending on the fluence of the laser beam. This reveals that the crater size on the material varies according to the pulse energy of the laser beam under the same optical spot size. Equation (2) shows the relationship between the diameter of the crater and the optical focal spot size, which is used to derive the threshold fluence.

In the previous section, we introduced the radius of the crater ($r_d$), which is a component of Eq. (2) and is used to determine the threshold fluence ($F_{th}$). Figure 5 presents a comparison of the converged crater diameters in copper obtained from experiments and simulations with an increase of the incident laser fluence ($F$) and the threshold fluence ($F_{th}$). The experimental results agree well with the simulations results at a threshold fluence of $0.075 \ J/cm^2$ as expressed by the solid line. This shows that the threshold fluence ($F_{th}$) at the wavelength of 515 nm was smaller than a quarter of that at a wavelength of 1064 nm [4].
4.2 Penetration depth

The volume ablation rate \( \frac{dV}{dt} \) represented in Eq. (1) has a functional relation with the driven threshold fluence \( F_{th} \) and the penetration depth \( \delta = \frac{1}{\alpha} \), as shown in Eq. (3). That is, it is possible to determine the penetration depth by substituting the function of the fluence and the ablation depth per pulse.

Figure 6 shows a cross-sectional profile of a crater that was processed under the conditions of 200 pulses and a fluence \( F \) of 0.28 J/cm\(^2\). The ablation depth was 12.2 \( \mu \)m and the processing depth per pulse \( L \) was 61 nm. Here, the derived penetration depth \( \delta \) result is 46 nm after using the fluence \( F \), the processing depth per pulse \( L \) and the threshold fluence \( F_{th} \) derived in the previous section by substituting Eq. (3). This indicates there is an increase in depth of 50% or more compared to the penetration depth of 30 nm, which was determined at a wavelength of 1064 nm \[4\]. The deeper penetration depth in the case of using the green wavelength (515 nm) can be ascribed to its higher absorption rate as compared with the near-infrared wavelength (1064 nm). This is intimately linked with that the threshold fluence \( F_{th} \) at the wavelength of 515nm was smaller than a quarter of that at a wavelength of 1064nm.

4.3 Dependency of volume ablation rate

In our previous work, Equation (1) was defined in order to maximize the volume ablation rate by deriving the penetration depth \( \delta \) and the threshold fluence \( F_{th} \) by experimental verification. Consequently, we could predict the volume ablation rate with an increase of repetition rate.

Figure 7 shows a relative comparison between the simulated ablation rate and arbitrary ablation depth as determined by the experiment with an increase of the repetition rate and the average power.

Figure 8 shows the three-dimensional profile of a surface that has been ablated under conditions referred to as (a) and (b) in Fig.7. Here, the relative comparison for ablation depth shows the ratio of the ablation depth when the maximum depth is 1 under conditions of an average power of 3.2 W and a repetition rate of 400 kHz. When the ablation depth of 150.5 \( \mu \)m for the conditions marked (a) is 1, the ablation depth of 109.2 \( \mu \)m becomes 0.72 for the conditions marked (b), as shown in Fig. 8. At this point, the experimental results show that the parameters used in Fig. 7 (b) are more efficient than those of Fig. 7 (a). Additionally, the ablation rate rises and falls at some point with an increase of the repetition rate under each average power.

Here, the highest ablation rate can be obtained in the region where the efficiency of the processing is maximized. Moreover, each average power has a corresponding point for the highest ablation rate with an increasing repetition rate. That is, average power of 3.2 W has a maximum ablation rate at a 446 kHz repetition rate, while with 1.6 W and 0.8 W average power, the respective highest points are reached under repetition rates of 223 kHz and 112 kHz.

This shows that the repetition rate is accompanied by a proportional increase of the average power. That is, the pulse energy, which is determined by dividing the average power by the repetition rate, remains constant. In consequence, the pulse energy is 7.17 \( \mu \)J. The fluence, which is defined by the pulse energy per unit area, is 0.28 J/cm\(^2\). This is also smaller than a quarter of that at a wavelength of 1064nm as shown in a prior study \[4\].

4.4 Patterning process using an optimized fluence

Figure 9 shows the embossed pattern on a copper block produced using a laser beam with a fluence of 0.28 J/cm\(^2\), which is the optimum condition in terms of efficiency obtained from the above experiment. The experimental result
verified that this cold ablation process could be achieved because the fluence for the maximum volume ablation rate is only four times the threshold fluence. However, there is a limitation in terms of productivity, because the average power was only 0.75 W for inducing a fluence of 0.28 J/cm² under the limited repetition rate of 100 kHz. In order to increase productivity, it is necessary to increase the average power and repetition rate proportionally. For example, the repetition rate is required to be 1 MHz in the case of an average power of 7.5 W under the same fluence and pulse energy.

At this point, when using extremely high repetition, heat accumulation becomes a concern. It is thus necessary to use faster scanning techniques to minimize the thermal effects under a higher repetition rate. This topic will be introduced in a future study.

5. Conclusions

This research attempted to verify the ablation efficiency of an ablation process on copper using a 515 nm wavelength ultra-short pulse laser. A theoretical analysis based on the obtained copper ablation experimental data showed that using a 515 nm picosecond laser instead of a 1064 nm picosecond laser is favorable. Specifically, the calculated threshold fluence is 75 % lower and the optical penetration depth is 50 % greater with the 515 nm picosecond laser. Finally, we were able to obtain a completely neat and clean micro-patterned surface based on optimized parameters determined for the 515 nm picosecond laser. However, in order to increase productivity, it will be necessary to increase the average power and the repetition rate proportionally and use faster scanning techniques to minimize the thermal effects under the higher repetition rate. This topic will be introduced in a future study.
